## Abstract

## 1 Introduction

Surface-level ozone ( $O_3$ ) is a secondary air pollutant formed from the photochemical degradation of volatile organic compounds (VOCs) in the presence of nitrogen oxides ( $NO_x$ ). Due to the photochemical nature of ozone production, meteorological factors such as temperature strongly influence ozone production (Jacob and Winner, 2009). Temperature influences ozone production through temperature-dependent emissions of VOC from biogenic sources (anthropogenic emissions are typically not temperature dependent) and the reaction rates of many of the chemical reactions involved in producing ozone are also temperature dependent. The recent review of Pusede et al. (2015) provides a detailed description of the temperature-dependent processes impacting ozone production. A recent study by indicates that temperature is a major meteorological driver for ozone in central europe.

Many studies over the US (Sillman and Samson, 1995; Dawson et al., 2007; Pusede et al., 2014) have observed the relationship between ozone and temperature, noting that increased temperatures tend to lead to higher ozone levels, often exceeding local air quality guidelines. Some of these studies (Sillman and Samson, 1995; Dawson et al., 2007) include modelling experiments using regional chemical transport models which have indeed verified the observed increases in ozone with temperature. The increase in the thermal decomposition rate of PAN (peroxy acetyl nitrate) with temperature is commonly cited for the increase of ozone with temperature.

Noelia's  
paper

Environmental chamber studies have looked at the relationship of ozone with temperature using a particular mixture of VOCs. The chamber experiments of Carter et al. (1979) and Hatakeyama et al. (1991), also showed increases in ozone with temperature and have also linked this relationship to increased PAN decomposition at higher temperatures ( $T > 303$  K). Hatakeyama et al. (1991) looked primarily at the influence of  $\text{HO}_2\text{NO}_2$  decomposition on ozone production and induced that at lower temperatures ( $T < 303$  K)  $\text{HO}_2\text{NO}_2$  decomposition has a large influence on ozone production but the influence of PAN decomposition on ozone production increases with temperature.

Pusede et al. (2014) used observations over the San Joaquin Valley, California to infer a non-linear relationship of ozone production with temperature and  $\text{NO}_x$ , similar to the well-known non-linear relationship of ozone production on  $\text{NO}_x$  and VOC levels (Sillman, 1999). In fact, Pusede et al. (2014) show that temperature can be used as a surrogate for VOC levels when looking at the relationship of ozone across  $\text{NO}_x$  gradients. Moreover, the described relationship of ozone on both  $\text{NO}_x$  and temperature needs to be considered when looking at effective strategies to reduce levels of surface ozone.

Despite a wealth of studies looking at the effects of temperature on ozone chemistry, there have not been (to our knowledge) modelling studies focusing on these effects across different  $\text{NO}_x$  gradients and whether the observed relationships are well-represented by different chemical mechanisms used in air quality models. The review of Pusede et al. (2015) also highlights a lack of modelling studies looking at this non-linear relationship of ozone on temperature across  $\text{NO}_x$  gradients. In this study, we use an idealised box model to determine how ozone levels vary with temperature and across  $\text{NO}_x$  gradients. We separate the effects of temperature-dependent chemistry and VOC emissions on ozone production by performing simulations including a temperature-independent source of isoprene followed by simulations using a temperature-dependent source of isoprene.

The study of Rasmussen et al. (2013) looking at the change of ozone with temperature in California (termed the “Ozone-Climate Penalty”) indicates that changing the chemical mechanism used by a model may also change the Ozone-Climate Penalty and should be investigated. Finally, by repeating these simulations with different chemical mechanisms, we determine whether the temperature dependence of ozone production is reproduced across different  $\text{NO}_x$  gradients in these chemical mechanisms.

## 2 Methodology

### 2.1 Model Setup

All simulations were performed using the MECCA box model, originally described in Sander et al. (2005), as set up in Coates and Butler (2015) to broadly simulate urban conditions of central Europe. In this study, MECCA box model was further updated to include vertical mixing with the free troposphere and included a diurnal cycle for the PBL height based on the data from the BAERLIN 2014 campaign over Berlin, Germany (Bonn and et.al., 2016). The supplementary material includes further details about these updates.

Simulations were performed using equinoctical conditions and started at 06:00 with a run time of two days. Methane was fixed at 1.7 ppmv throughout the model run, carbon monoxide (CO) and ozone were initialised at 200 ppbv and 40 ppbv and then allowed to evolve freely throughout the the simulation. All VOC emissions were held constant until noon of first day, to simulate a plume of emitted VOC.

Model runs were repeated using a temperature-dependent and temperature-independent source of biogenic VOC (BVOC) emissions. MEGAN2.1 (Guenther et al., 2012) was used to specify the temperature-dependent BVOC emissions of isoprene, Sect. 2.3 provides further details. We focus only on isoprene as isoprene is the most important BVOC on the global scale due its high emission rates and emissions from vegetation are dependent on temperature (Guenther et al., 2006). In reality, increased temperature can also increase anthropogenic VOC (AVOC) emissions through increased evaporation.

All simulations were repeated using different chemical mechanisms to investigate how well the relationship of ozone with temprature across  $\text{NO}_x$  gradients is represented. The reference chemical mechanism is the near-explicit Master Chemical Mechanism, MCMv3.2, (Jenkin et al., 1997), (Jenkin et al., 2003), (Saunders et al., 2003), (Rickard et al., 2015). The reduced chemical mechanisms in our study are Common Representative Intermediates, CRIv2 (Jenkin et al., 2008), Model for ozone and related chemical tracers, MOZART-4 (Emmons et al., 2010), Regional Acid Deposition Model, RADM2 (Stockwell et al., 1990) and the Carbon Bond Mechanism, CB05 (Yarwood et al., 2005). Coates and Butler (2015) describes these chemical mechanisms and the implementation of these chemical mechanisms in MECCA. These reduced chemical mechanisms were chosen as they are commonly used by modelling groups in 3D regional and global models.

The temperature was systematically varied between 288 and 313 K (15 – 40 °C). The only

Table 1: Total AVOC emissions in 2011 in tonnes from each SNAP category assigned from TNO-MACC\_III emission inventory and temperature-independent biogenic VOC emission in tonnes from Benelux region assigned from EMEP. The allocation of these emissions to MCMv3.2, CRIv2, CB05, MOZART-4 and RADM2 species is found in the supplementary material.

source of NO<sub>x</sub> emissions in the box model was a constant source of NO emissions. The NO emissions were systematically varied from  $5.0 \times 10^9$  to  $1.5 \times 10^{12}$  molecules (NO) cm<sup>-2</sup> s<sup>-1</sup> at each temperature used in this study.

## 2.2 VOC Emissions

Typical emissions of urban AVOC over central Europe were taken from TNO-MACC\_III emission inventory from the Benelux (Belgium, Netherlands and Luxembourg) region for the year 2011. TNO-MACC\_III is the current version of the TNO-MACC\_II inventory created using the same methodology as Kuenen et al. (2014) and based upon improvements to the existing emission inventory during the AQMEII-2 exercises described in Pouliot et al. (2015).

Temperature-independent emissions of the biogenic VOC isoprene and monoterpenes, were calculated as a fraction of the total AVOC emissions from each country in the Benelux region. This data was obtained from the supplementary data available from the EMEP (European Monitoring and Evaluation Programme) model (Simpson et al., 2012). Temperature-dependent emissions of isoprene are detailed in Sect. 2.3.

The AVOC emissions from the emission inventory were allocated to SNAP (Selected Nomenclature for Air Pollution) source categories and these category emissions were assigned to chemical species and groups based on the country specific profiles for Belgium, the Netherlands and Luxembourg provided by TNO. Table 1 shows the tonnes of NMVOC emissions from each SNAP category and the temperature-independent BVOC emissions.

In order to represent the AVOC emissions from each SNAP category in the MCMv3.2,

the same approach as described in von Schneidemesser et al. (2016) was used. In summary, most individual chemical species are represented by the MCMv3.2 otherwise the individual contributions of a group of NMVOC were further split into individual components using the detailed speciation of Passant (2002). For example, ‘xylenes’ are one of the component chemical groups to many SNAP categories but the MCMv3.2 treats xylenes by the individual isomers (m-, o-, p-xylene) and the individual contributions of the individual isomers to a SNAP category was provided by Passant (2002).

Again similarly to von Schneidemesser et al. (2016), the NMVOC emissions were first assigned to chemical species represented by the MCMv3.2 and then mapped to the mechanism species representing NMVOC emissions in the reduced chemical mechanisms. The NMVOC emissions in the reduced chemical mechanisms were weighted by the carbon numbers of the MCMv3.2 species and the emitted mechanism species. The supplementary data outlines the primary NMVOC and calculated emissions with each chemical mechanism.

## 2.3 Temperature Dependent Isoprene Emissions

Temperature-dependent emissions of isoprene were estimated using the MEGAN2.1 model for calculating the emissions of VOC from vegetation (Guenther et al., 2012). Emissions from plants are dependent on variables including temperature, radiation and age but for the purpose of our study we are only interested in the effects of temperature, hence all variables except temperature were held constant.

The MEGAN2.1 parameters were chosen to give similar isoprene mixing ratios at 20 °C to the temperature-independent emissions, enabling an adequate comparison of the effects of increased isoprene emissions from the temperature-independent case. The estimated emissions of isoprene with MEGAN2.1 using these assumptions, are illustrated in Fig. 1 and show the expected exponential increase in emissions with temperature (Guenther et al., 2006).

To verify whether our inputs to calculating isoprene emissions using MEGAN2.1, we compare the simulated isoprene mixing ratios to those measured from over the urban area of Essen, Germany (Wagner and Kuttler, 2014). At 20 °C, the estimated emissions of isoprene lead to 0.07 ppbv of isoprene in our model while at 30 °C, the increased emissions of isoprene using MEGAN2.1 estimations lead to 0.35 ppbv of isoprene in the model. In the measurement campaign over Essen, 0.1 ppbv of isoprene were measured at temperatures of 20 °C and 0.3 ppbv of isoprene were measured at 30 °C. This comparison indicates that the values chosen for calculating the

Figure 1: The estimated isoprene emissions (molecules isoprene  $\text{cm}^{-2} \text{s}^{-1}$ ) at each temperature step used in the study. Isoprene emissions were estimated using the MEGAN2.1 algorithm (Guenther et al., 2012).

138 temperature-dependent emissions of isoprene with MEGAN2.1 lead to reasonable values of  
 139 isoprene mixing ratios.

### 140 3 Results and Discussion

#### 141 3.1 Ozone mixing ratios as function of NO<sub>x</sub> and Temperature

142 Figure 2 depicts the maximum mixing ratio of ozone as a function of the total NO<sub>x</sub> emissions on  
 143 the first day and temperature when using temperature-independent and temperature-dependent  
 144 source of isoprene emissions for each chemical mechanism. A non-linear relationship of ozone  
 145 mixing ratios with NO<sub>x</sub> and temperature is reproduced by each chemical mechanism. This  
 146 non-linear relationship has a similar form to that determined by Pusede et al. (2014) using an  
 147 analytical model constrained to observational measurements over the San Joaquin Valley in  
 148 California.

Figure 2: Contours of maximum ozone mixing ratio as a function of the total  $\text{NO}_x$  emissions on the first day and temperature for each chemical mechanism and using both a temperature-dependent and -independent source of isoprene emissions.

Figure 3: Ozone mixing ratios at each temperature are allocated to different  $\text{NO}_x$ -regimes of Fig. 2. The differences in ozone mixing ratios due to chemistry and emissions of Table 2 are represented graphically for MOZART-4, the approach was used to calculate the differences with each chemical mechanism.

The highest mixing ratios of ozone in Fig. 2 are produced at higher temperatures and high- $\text{NO}_x$  conditions, also ozone mixing ratios increase when using a temperature-dependent source of isoprene emissions. Conversely, the least amount of ozone is produced with low- $\text{NO}_x$  conditions over the whole temperature range (15 – 40  $^{\circ}\text{C}$ ) when using both a temperature-independent and temperature-dependent source of isoprene emissions.

The non-linear relationship of ozone with  $\text{NO}_x$  and temperature can be split into three  $\text{NO}_x$ -regimes (low- $\text{NO}_x$ , maximal- $\text{O}_3$  and high- $\text{NO}_x$ ) based on the ratio of  $\text{HNO}_3$  to  $\text{H}_2\text{O}_2$  used in Sillman (1995) to determine  $\text{NO}_x$ -regimes for the non-linear relationship of ozone with  $\text{NO}_x$  and VOC. The low- $\text{NO}_x$  regime corresponds to the lower-left most area in Fig. 2 where there is little increase in ozone with temperature, also called  $\text{NO}_x$ -sensitive conditions. The high- $\text{NO}_x$  regime is when ozone levels increase rapidly with temperature in Fig. 2, sometimes called  $\text{NO}_x$ -saturated conditions. Finally, the ridges of the contours in Fig. 2 correspond to maximal-ozone production and we call this the maximal- $\text{O}_3$  regime. The ozone mixing ratios obtained in each simulation were assigned to a  $\text{NO}_x$  regime based on the  $\text{H}_2\text{O}_2:\text{HNO}_3$  of the simulation and Fig. 3 illustrates the mean ozone mixing ratio at each temperature in these  $\text{NO}_x$  regimes.

Table 2: Increase in ozone mixing ratio (ppbv) due to chemistry and emissions at 40 °C from reference temperature (20 °C) in the NO<sub>x</sub>-regimes of Fig. 2.

Chemical Mechanism	Source of Difference	Increase in Ozone at 40 °C from 20 °C (ppbv)		
		Low-NO <sub>x</sub>	Maximal-O <sub>3</sub>	High-NO <sub>x</sub>
MCMv3.2	Chemistry	6.8	12.5	15.2
	Emissions	4.6	7.7	10.6
CRIV2	Chemistry	6.0	11.1	13.7
	Emissions	4.8	7.9	10.8
MOZART-4	Chemistry	6.0	10.2	12.3
	Emissions	4.1	6.7	10.0
CB05	Chemistry	9.3	16.0	19.9
	Emissions	4.6	7.4	9.8
RADM2	Chemistry	8.6	14.1	17.3
	Emissions	3.8	5.7	7.8

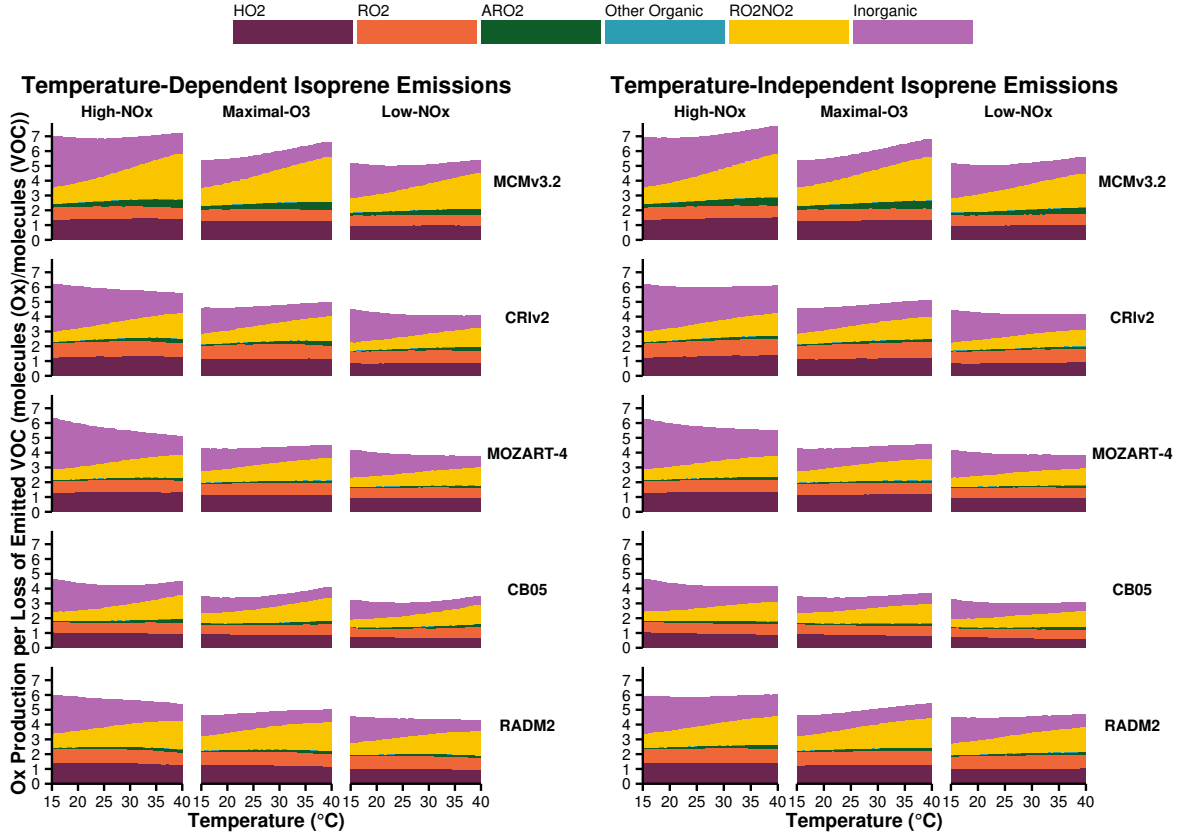

Calculating the difference in ozone mixing ratios at 40 °C from 20 °C when using a temperature-independent source of isoprene emissions gives the absolute increase in ozone due to faster chemistry. When using a temperature-dependent source of isoprene emissions, the difference in ozone mixing ratios at 40 °C from 20 °C less the increase due to faster chemistry, gives the absolute increase in ozone due to increased isoprene emissions. These differences are represented graphically in Fig. 3 and summarised in Table 2.

Both Fig. 3 and Table 2 highlight that the absolute increase in ozone at 40 °C from 20 °C is largest with high-NO<sub>x</sub> conditions. The increase in ozone mixing ratio at 40 °C from 20 °C due to faster chemistry with high-NO<sub>x</sub> conditions is almost double that with low-NO<sub>x</sub> conditions. We shall explore which chemical processes are responsible for the increases in ozone mixing ratios at 40 °C from 20 °C by analysing O<sub>x</sub> production budgets in Sect. 3.2.

Comparing the response of ozone mixing ratios to temperature in the reduced chemical mechanisms (CRIV2, MOZART-4, CB05 and RADM2) to the near-explicit MCMv3.2 chemical mechanism shows that the largest differences from the MCMv3.2 occur in the maximal-O<sub>3</sub> and high-NO<sub>x</sub> regimes. Table 2 also indicates that all reduced chemical mechanisms, except RADM2, have similar increases in ozone due to temperature-dependent isoprene emissions to MCMv3.2. RADM2 produces 3 ppbv less ozone than the MCMv3.2 due to temperature-dependent isoprene emissions consistently in each NO<sub>x</sub> regime, indicating that this difference is due to how isoprene degradation chemistry is treated in RADM2.

The Tagged Ozone Production Potential (TOPP) of isoprene is a measure of the number of molecules of ozone produced per molecule of isoprene emitted and Coates and Butler (2015) shows that less ozone is produced from isoprene degradation using RADM2 than with MCMv3.2.

Figure 4: Day-time  $O_x$  production budgets normalised by the total oxidation rate of emitted VOC in the  $NO_x$ -regimes of Fig. 2. The budgets are allocated to the categories of inorganic reactions, peroxy nitrate ( $RO_2NO_2$ ) decomposition, reactions of  $NO$  with  $HO_2$ , alkyl peroxy radicals ( $RO_2$ ) and acyl peroxy radicals ( $ARO_2$ ). All other reactions contributing to  $O_x$  budgets are allocated to ‘Other Organic’.

The degradation of isoprene has been extensively studied and it is well-known that the species methyl vinyl ketone (MVK) and methacrolein are signatures of isoprene degradation. All chemical mechanisms used in our study do explicitly include MVK and methacrolein (or in the case of CB05, a lumped species representing both these secondary degradation products) production during isoprene degradation except RADM2. RADM2 does not include methacrolein and the ketone species included in RADM2 represents a mixture of acetone and methyl ethyl ketone (MEK), thus the secondary degradation of isoprene in RADM2 is unable to represent the ozone production from the further degradation of its signature degradation products MVK and methacrolein. More recent versions of RADM2, RACM (Stockwell et al., 1997) and RACM2 (Goliff et al., 2013), sequentially include methacrolein and MVK and with these updates the TOPP values of isoprene reported in Coates and Butler (2015) are similar to the TOPP value of isoprene in the MCMv3.2.

## 3.2 Ozone Production Budgets

In order to determine which chemical processes are causing the increase in ozone with temperature (Sect. 3.1), we analyse the  $O_x$  production budgets in each  $NO_x$  regime (low- $NO_x$ , Maximal- $O_3$  and high- $NO_x$ ) defined in Sect. 3.1. We defined the  $O_x$  family to consist of  $O_3$ ,  $NO_2$  and  $O$ , and Fig. 4 displays the total day-time  $O_x$  production budgets normalised by the total initial oxidation rates of the emitted NMVOC for each chemical mechanism within each  $NO_x$  regime. The  $O_x$  production budgets in Fig. 4 are allocated to the major sources, where ‘HO2’, ‘RO2’, ‘ARO2’ represent the reactions of NO with  $HO_2$ , alkyl peroxy radicals and acyl peroxy radicals respectively. ‘RO2NO2’ represents the thermal decomposition of peroxy nitrates, ‘Inorganic’ represents all inorganic contributions to the  $O_x$  production budgets (primarily the de-excitation of  $O^1D$  to  $O$ ) and any other remaining organic reactions producing  $O_x$  are included in the ‘Other Organic’ category.

In Fig. 4 the number of molecules of  $O_x$  produced per molecule of NMVOC oxidised in High- $NO_x$  conditions is similar when using temperature-dependent or temperature-independent isoprene emissions for each chemical mechanism; the same is also true for the Maximal- $O_3$  and Low- $NO_x$  regimes. Thus the increases in isoprene emissions in the temperature-dependent simulations are balanced by the faster oxidation rates of the emitted NMVOC. The highest amount of  $O_x$  is produced in the High- $NO_x$  regime and the lowest amount of  $O_x$  is produced in the Low- $NO_x$  regime, mirroring the  $O_3$  mixing ratios in the different  $NO_x$  regimes in Fig.3. For example, when using MCMv3.2 seven molecules of  $O_x$  are produced per molecule of NMVOC oxidation in High- $NO_x$  conditions, decreased to about six and five molecules of  $O_x$  produced per molecule of NMVOC oxidised in the Maximal- $O_3$  and Low- $NO_x$  regimes. In each  $NO_x$  regime, all the reduced chemical mechanisms produce up to two molecules of  $O_x$  per molecule of emitted NMVOC oxidised less than the MCMv3.2.

Turning to the individual contributions to the normalised production of  $O_x$  in Fig. 4, peroxy nitrate (RO2NO2) decomposition and inorganic reactions show a strong (and opposing) dependence on temperature in all  $NO_x$  regimes, each chemical mechanism and regardless of the source of isoprene emissions. Whereas the contributions of the reaction of NO with the peroxy radicals (HO2, RO2 and ARO2 in Fig. 4) to the normalised production budgets of  $O_x$  do not increase strongly with temperature indicating that these processes are strongly related to the faster oxidation of the emitted NMVOC with temperature.

### 3.2.1 Peroxynitrates

We shall now turn our focus to the peroxy nitrate ( $\text{RO}_2\text{NO}_2$ ) contribution as this category has a strongly temperature-dependent contribution to the normalised  $\text{O}_x$  production. Peroxy nitrates are an important reservoir species for both peroxy radicals and  $\text{NO}_x$  that are formed from the reactions of alkyl and acyl peroxy nitrates with  $\text{NO}_2$  (Reaction R1).

The chemical bond of  $\text{RO}_2\text{NO}_2$  is quite weak with thermal decomposition being the most important chemical reaction and thermal decomposition depends strongly on temperature. At low temperatures,  $\text{RO}_2\text{NO}_2$  can accumulate and be transported downwind of emissions of the sources of its precursors (NMVOC and  $\text{NO}_x$ ), after thermal decomposition the release of  $\text{NO}_2$  and peroxy radicals can promote production of  $\text{O}_3$  downwind (Moxim et al., 1996).

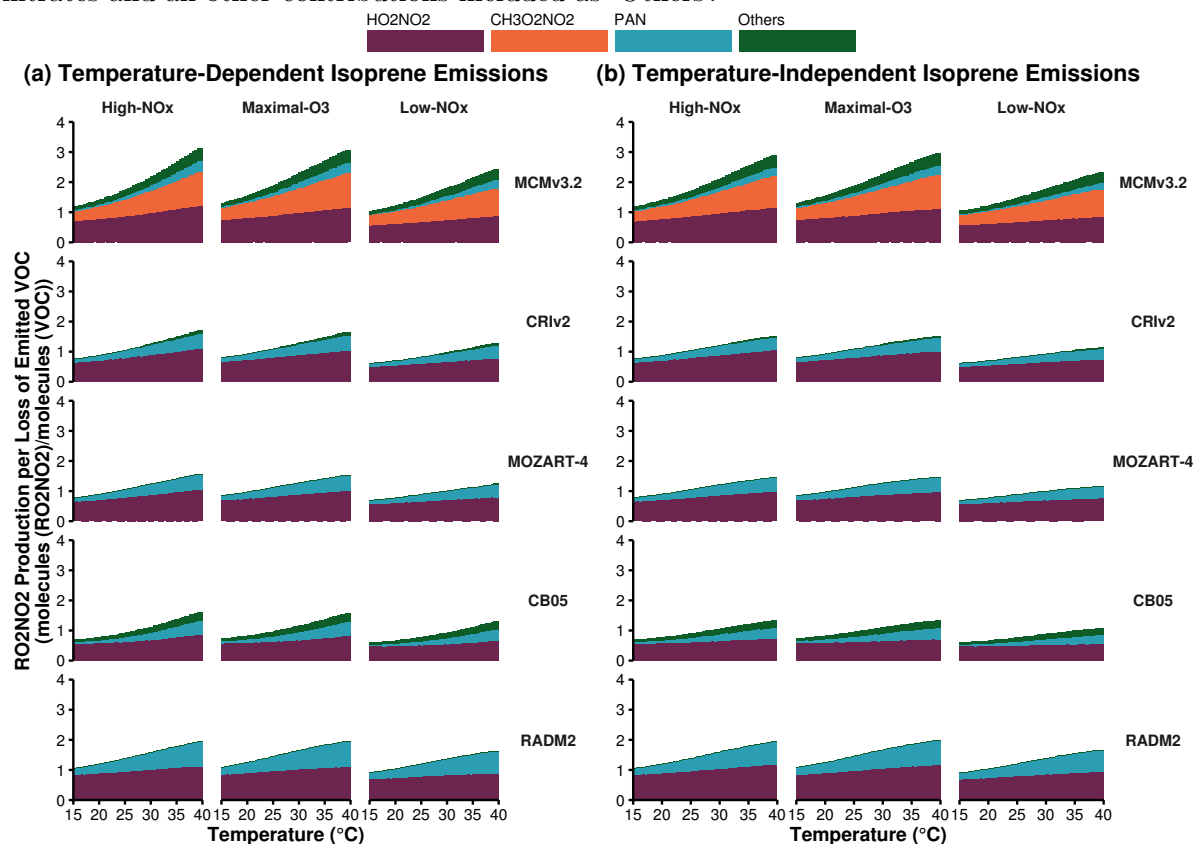

Peroxy nitrates are formed from both alkyl and acyl peroxy radicals, with the acyl peroxy radicals being more thermally stable than the alkyl peroxy nitrates. The most important alkyl peroxy nitrates are pernitric acid ( $\text{HO}_2\text{NO}_2$ ) and methylperoxy nitrate ( $\text{CH}_3\text{O}_2\text{NO}_2$ ), while peroxy acetyl nitrate (PAN,  $\text{CH}_3\text{C}(\text{O})\text{O}_2\text{NO}_2$ ) and peroxy propionyl nitrate (PPN,  $\text{C}_2\text{H}_5\text{C}(\text{O})\text{O}_2\text{NO}_2$ ) are important acyl peroxy nitrates.

The alkyl peroxy nitrates have a weaker  $\text{RO}_2\text{--NO}_2$  bond than acyl peroxy nitrates hence alkyl peroxy nitrates have a shorter lifetime than acyl peroxy nitrates. For example,  $\text{CH}_3\text{O}_2\text{NO}_2$  has a lifetime of 0.5 seconds at 298 K while PAN has a lifetime of 51 minutes at 298 K (Orlando and Tyndall, 2012).

Each chemical mechanism used in our study represents  $\text{HO}_2\text{NO}_2$  and PAN, although in many reduced chemical mechanisms PAN represents  $\text{CH}_3\text{C}(\text{O})\text{O}_2\text{NO}_2$  and other acyl peroxy nitrates. This representation of PAN in reduced chemical mechanisms can lead to overestimations of PAN levels compared to more detailed chemical mechanisms (Luecken et al., 1999). The near-explicit MCMv3.2 represent a diverse range of peroxy nitrates including  $\text{CH}_3\text{O}_2\text{NO}_2$  and about 280 acyl peroxy nitrates.

Figure 5 displays the normalised production budgets of  $\text{RO}_2\text{NO}_2$  by the total loss rate of the emitted NMVOC, similar to Fig. 4 for each chemical mechanism in each  $\text{NO}_x$  regime and when using a temperature-independent and temperature-dependent source of isoprene emissions. The large contribution of  $\text{CH}_3\text{O}_2\text{NO}_2$  in MCMv3.2 is not mirrored in any reduced chemical

Figure 5: Day-time  $\text{RO}_2\text{NO}_2$  production budgets normalised by the total oxidation rate of emitted VOC in the  $\text{NO}_x$ -regimes of Fig. 2. The total budgets are allocated to the most important peroxy nitrates and all other contributions included as ‘Others’.

mechanism as  $\text{CH}_3\text{O}_2\text{NO}_2$  is not represented in any of the reduced chemical mechanisms. In fact the number of molecules of  $\text{RO}_2\text{NO}_2$  per molecules of NMVOC oxidised in each reduced chemical mechanism is very similar to that of MCMv3.2 less the contribution of  $\text{CH}_3\text{O}_2\text{NO}_2$  for the separate  $\text{NO}_x$  regimes and regardless of isoprene source.

The contribution of  $\text{RO}_2\text{NO}_2$  to the normalised  $\text{O}_x$  production in Fig. 4 is largest in the MCMv3.2 than the reduced chemical mechanisms due to the representation of  $\text{CH}_3\text{O}_2\text{NO}_2$  in the MCMv3.2. If reduced chemical mechanisms represent  $\text{CH}_3\text{O}_2\text{NO}_2$  chemistry then this would improve the representation of the total  $\text{RO}_2\text{NO}_2$  production which would have the added effect of improving the representation of  $\text{O}_x$  production budgets.
